Abstract

Abstract here.

Introduction

The fields of catalysis and materials science are burgeoning with research articles that use machine learning and data science to screen, design, and understand materials.^{1–4} This research has spurred the creation of machine learning models to predict various material properties. Unfortunately, the design spaces for these models are sometimes too large and intractable to sample completely. These undersampling issues can limit the training data and therefore the predictive power of the models. It would be helpful to have an uncertainty quantification (UQ) for a model so that we know when to trust the predictions and when not to. More specifically: UQ would enable various online, active frameworks for materials

discovery and design (e.g., active learning,⁵ online active learning,⁶ Bayesian optimization,⁷ active search,⁸ or goal oriented design of experiments⁹).

Such active frameworks have already been used successfully in the field of catalysis and materials informatics. For example: Peterson¹⁰ has used a neural network to perform online active learning of nudged elastic band (NEB) calculations, reducing the number of force calls by an order of magnitude. Torres et al.¹¹ have used also used online active learning to accelerate NEB calculations, but they used a Gaussian Process (GP) model instead of a neural network. Jinnouchi et al.¹² have used online active learning to accelerate molecular dynamics simulations. Each of these active methods are underpinned by models with UQ, which has garnered increasing attention itself.^{13,14}

To our knowledge though, we have not seen many comparisons of different methods for UQ within the field of catalysis and materials informatics. Here we attempt to resolve this issue by benchmarking six different methods for UQ (Figure 1). We acknowledge that there will not be one optimal method across all use cases, but we still find value in sharing these results so that others can build intuition from our results. Perhaps more importantly, we have also established a protocol for comparing the performance of different modeling and UQ methods.

Methods

Data handling

All regressions in this paper were performed on a dataset of Density Functional Theory (DFT) calculated adsorption energies created with the Generalized Adsorption Simulator for Python (GASpy).^{15,16} These data included energies from 21,269 different H adsorption sites; 1,594 N sites; 18,437 CO sites; 2,515 O sites; and 3,464 OH sites; totaling in 47,279 data points. GASpy performed all DFT calculations using the Vienna Ab-initio Simulation Package (VASP)^{17–20} version 5.4 implemented in the Atomic Simulation Environment

Figure 1: Placeholder for overview of the paper

(ASE).²¹ The revised Perdew-Burke-Ernzerhof (rPBE) functionals²² were used along with VASP’s pseudopotentials, and no spin magnetism or dispersion corrections were used. Bulk relaxations were performed with a $10 \times 10 \times 10$ k-point grid and a 500 eV cutoff, and only isotropic relaxation were allowed during this bulk relaxation. Slab relaxations were performed with k-point grids of $4 \times 4 \times 1$ and a 350 eV cutoff. Slabs were replicated in the X/Y directions so that each cell was at least 4.5 Å wide, which reduces adsorbate self-interaction. Slabs were also replicated in the Z direction until they were at least 7 Å thick, and at least 20 Å of vacuum was included in between slabs. The bottom layers of each slab were fixed and defined as those atoms more than 3 Å from the top of the surface in the scaled Z direction.

To split the data into train/validate/test sets, we first enumerated all adsorption energies on monometallic slabs and added them to the training set manually. We did this because some of the regression methods in this paper use a featurization that contains our monometallic adsorption energy data,¹⁵ and so having the monometallic adsorption energies pre-allocated in the training set prevented any information leakage between the training set

and validation/test sets. After this allocation, we performed a 64/14/20 train/validate/test split that was stratified²³ by adsorbate. We then used the validation set’s results to tune various hyperparameters manually. After tuning, we calculated the training set results and present them in this paper exclusively.

Regression methods

1. CGCNN
2. CGCNN Ensemble
3. GP
4. GP with CGCNN
5. With other kernels too
6. Penultimate-Fed GP
7. Bayesian CGCNN with prior on weights at some layer
8. Supervised error prediction (delta CGCNN)
9. Dropout CGCNN

Performance metrics

We used six different metrics to quantify the accuracy of the various models: Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), Median Absolute Deviation (MDAE), Mean Absolute Relative Percent Difference (MARPD), R^2 correlation coefficient (R^2), and Pearson product-moment correlation coefficient (Pearson’s). MARPD values were calculated with Equation 1

$$MARPD = \frac{1}{N} \sum_{i=1}^N \left| 100 \cdot \frac{\hat{x}_n - x_n}{|\hat{x}_n| + |x_n|} \right| \quad (1)$$

where n is the index of a data point, N is the total number of data points, x_n is the true value of the data point, and \hat{x}_n is the model’s estimate of x_n . In this case, x_n is a DFT-calculated adsorption energy and \hat{x}_n is the surrogate-model-calculated adsorption energy. We used MDAE because it is insensitive to outliers and is therefore a good measure of accuracy for the majority of the data. We used RMSE because it is sensitive to outliers and is therefore a good measure of worst-case accuracy. We used MAE because it lies between MDAE and RMSE in terms of sensitivity to outliers. We used MARPD, R^2 , and Pearson’s because they provide normalized measures of accuracy that may be more interpretable for those unfamiliar with adsorption energy measurements in eV. The ensemble of these metrics provide a more robust view of accuracy than any one metric can provide alone.

To assess the calibration (or “honesty”) of these models’ UQs, we created calibration curves. A calibration curve “displays the true frequency of points in each [prediction] interval relative to the predicted fraction of points in that interval”, as outlined by Kuleshov et al.²⁴. In other words: We used the standard deviation predictions to create Gaussian-shaped prediction intervals around each test point, and then we compared these intervals to the models’ residuals at these points. If the residuals tended to fall outside the prediction intervals too often, then the UQs were considered overconfident. If the residuals tended to fall inside the prediction intervals too often, then the UQs were considered underconfident. Thus “well-calibrated” models had residuals that created a Gaussian distribution whose standard deviation was close to the model’s predicted standard deviations. We discuss calibration curves in more detail in the Results section alongside specific examples.

As Kuleshov et al.²⁴ also pointed out, well-calibrated models are necessary but not sufficient for useful UQs. For example: A well-calibrated model could still have large uncertainty estimates, which are inherently less useful than well-calibrated and small uncertainty estimates. This idea of having small uncertainty estimates is called “sharpness”, and Kuleshov

et al.²⁴ define it with Equation 2

$$sha = \frac{1}{N} \sum_{n=1}^N var(F_n) \quad (2)$$

where $var(F_n)$ is the variance of the cumulative distribution function F at point n . This is akin to the average variance of the uncertainty estimates on the test set. Here we propose a new formulation (Equation 3) where we add a square root operation. This operation gives the sharpness the same units as the predictions, which provides us with a more intuitive reference in the magnitude of the sharpness values.

$$sha = \sqrt{\frac{1}{N} \sum_{n=1}^N var(F_n)} \quad (3)$$

Results

1. Table/figure of metrics
2. Plots:
 - (a) parity
 - (b) calibration
 - (c) sharpness
3. Blocking results on best candidates (maybe put in SI)
4. Cost of computing each method (if its there)
5. Human overhead and difficulty

Conclusions

Observations about relative accuracies, calibrations, sharpnesses, overhead. Note that we did not do any calibration, and possibly provide references on how to do that if you wanted to.
